ABSTRACT

Introduction: Tuberculosis is one of the serious healthcare concerns of the world today. The only vaccine available for tuberculosis till date is the BCG vaccine. It is one of the safest vaccine and is less commonly associated with adverse effects. However, recently we have seen an upsurge in number of BCG vaccine associated lymphadenitis in our hospital. Objective: To report the increase in number of BCG associated lymphadenitis cases in our hospital. Materials and methods: A total of ten cases of BCG associated lymphadenitis were collected from the parents. Observations/Results: Out of the ten cases, 3 were vaccinated outside while the remaining infants were vaccinated in our hospital. Three out of the ten infants required intervention and remaining 7 were reassured and followed up, the swelling subsided in most of them. The most probable cause of the increased incidence in our hospital could be because of a particular batch of vaccine containing an altered strain/ change in the number of viable organism. Conclusion: We are reporting the cases as it might lead to an awareness among other practitioners and will also provide a scope for further studies. Increased surveillance and appropriate treatment guidelines for BCG vaccine associated lymphadenitis is the need of the hour.

Key words: Tuberculosis, BCG vaccine, lymphadenitis

INTRODUCTION

Tuberculosis (TB) is one of the major health problems in the current era. As per the WHO data, 10.4 million people were affected with TB and 1.8 million deaths due to TB in the year 2015. One million children (aged 0–14 years) fell ill with TB and 17,000 deaths were reported. The emerging multidrug resistant strains of TB bacilli is the prime concern related to treatment of TB. As a preventive measure, the only vaccine currently available is the BCG vaccine. There are few other vaccines which are currently under development. BCG vaccine prevents the disseminated forms of tuberculosis in children, including TB meningitis. It is one of the most widely used vaccine, reaching about more than 80% of neonates in countries where it is a part of the national immunization programme. In India, under the Expanded Programme of Immunization (EPI), BCG vaccine is given to all newborns at birth. There is no provision for booster doses under the programme. The various complications of BCG vaccine include regional suppurative/non suppurative lymphadenitis, eczema vaccinatum, lupoid reactions osteomyelitis/ositis and disseminated TB. Regional lymphadenitis is one of the common complications of BCG vaccine. However, in the past one year, we have noticed an increase in the number of BCG induced lymphadenitis in our hospital. Hence, we thought of reporting these 10 patients who presented to our outpatient department to create an increased awareness among the health care providers.

MATERIALS AND METHODS

We collected the data of 10 infants with signs of lymphadenopathy due to BCG vaccine who came to the paediatric outpatient department of Dr. TMA Pai Rotary Hospital, Karkala, Karnataka, India. Since data was collected retrospectively, it was not possible to take informed consent. Hence, we thought of reporting these 10 patients who presented to our outpatient department to create an increased awareness among the health care providers.

DISCUSSION

BCG vaccine associated lymphadenitis is defined as the development of ipsilateral regional lymph node enlargement after BCG vaccination and absence of local/ systemic signs of inflammation. Lymphadenitis can be of two types: 1) simple/ non suppurative- needs no intervention and patient’s parents have to be assured and it usually resolves on its own or sometimes may turn into suppurative form. 2) suppurative – this is a serious form. It can lead to rupture, sinus and later scar formation. To prevent these complications, sometimes surgical excision might be required.

In our hospital, BCG vaccine is administered intradermally. We have reported these cases because we found an increase in the number of cases of BCG associated lymphadenopathy in the past one year. There were 10 cases from May 2016 to April 2017. We had not seen any case of BCG induced lymphadenitis in the past 5 years in our hospital prior to these
cases. Information prior to that is not available. The various risk factors associated with BCG related lymphadenitis includes (i) Vaccine related factors: BCG strain used in the vaccine, dose, viability of organisms in the vaccine, skill of the personnel administering the vaccine. (ii) Host factors: age at vaccination, immunological response to vaccine, characteristics of recipient population.2 Of the factors mentioned above the probable cause of the increased incidence in our hospital could be the vaccine related (a particular batch of vaccine containing an altered strain/ number of viable organism). The vaccine used in our hospital is provided by the government of India under the national immunization programme. There was an incident of BCG induce lymphadenitis outbreak in Malaysia because of change in the strain of bacilli used in vaccine preparation.3 In the study they have mentioned that the increase in the incidence was due to the change in the vaccine strain from Tokyo-172 to Pasteur-1173. The authors also found that the Pasteur strain BCG vaccine had altered count of viable organisms. The incidence of lymphadenitis declined after the Tokyo strain was reintroduced. Glaxo 1077 and Tokyo 172 are “weak” strains, whereas Pasteur 1173 and Danish 1331 are “strong” strains. The incidence of lymphadenitis is higher with strong strains. We have not checked on the viable count of the BCG vaccine used to immunize infants in our hospital, hence cannot comment on this aspect. The other factors such as immunization technique, dose and the skill of the vaccine provider is probably not a reason because vaccine in our hospital is provided by trained nurses since the past two decades.

The concern with BCG lymphadenitis is that there is no clarity regarding the treatment of BCG induced lymphadenitis. Some physicians use antibiotics like erythromycin and antitubercular drugs and certain studies have shown them to be effective.4,5 However controlled studies have suggested that use of antibiotics neither reduces the risk of suppuration nor does it speed up healing.6,7,8,9,10 Since non supplicative lymphadenitis usually heals on its own, it is better not to start antibiotics as they have their own side effects.11 For supplicative lymphadenitis, it is advocated that needle aspiration causes rapid healing and prevents complications such as sinus and scar formation. Surgical excision is sometimes advised when needle aspiration fails as in case of mature and multiloculated lymphnodes or when there is already a sinus formation. These treatments are the suggestions of various authors based on their observations and studies, however there is lack of treatment guidelines for BCG induced lymphadenitis.

The other problem includes lack of clear case definition of BCG associated lymphadenitis. An unambiguous case definition would help the health care providers to identify the cases correctly. There is also a need for increase in the surveillance for detection of cases because most of these cases might go undetected as they usually subside without any medical intervention. The vaccine purity check should also be made more stringent emphasizing on the control of viability of organisms.

CONCLUSION

A recent increase in the number of cases of BCG vaccine induced lymphadenitis in our hospital was seen over past few months, the reason for which is still unknown. We would encourage other health care professionals to report similar cases. Further detailed studies needs to be conducted to find out exact cause of increased incidence in cases and the most appropriate way to deal with it. BCG vaccine is administered to more than 80% of infants in our country hence increase in the incidence of adverse effects is a matter of grave concern as this might have detrimental effects on attitude of parents towards vaccination.

CONFLICTS OF INTEREST

The authors declare no conflict of interest.
